# Project Outline

Introduction

Architecture

Implementation

Database Design

Conlusion

# Context

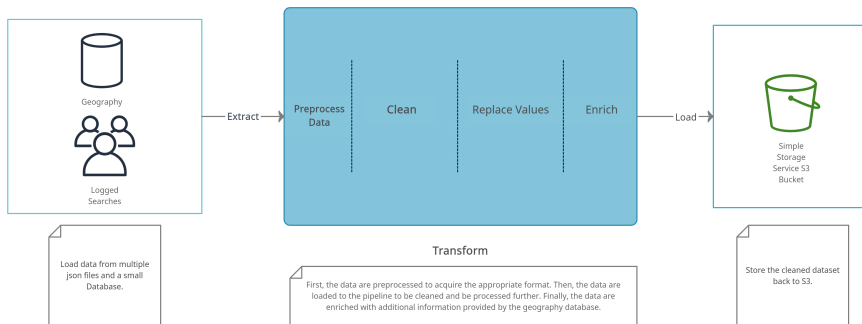

1. SpaN is a company that provides an online portal for real estate services.
2. Strategy department of SpaN needs to process the logged property searches acquired by users based on certain criteria.
3. The design of a data lake and the appropriate pipeline is necessary for better analysis of the data by the Strategy team.
4. The project consists of three distinct parts (Architecture, Implementation, Database Design).

# Data & Dataflows

1. The data provided, consisted of a relational database with geographical information, and a series of files, containing user searches logged in a json format.
2. After the preprocessing, appropriate transformations of the data follow, along with the extraction of the useful attributes according to the given specifications.
3. The data are enriched with information provided by the second data source, the geography database.
4. Finally, the final dataset is stored in the appropriate format, in order to be used efficiently.
5. An overview of my approach follows in the next slide.

# Architecture Diagram

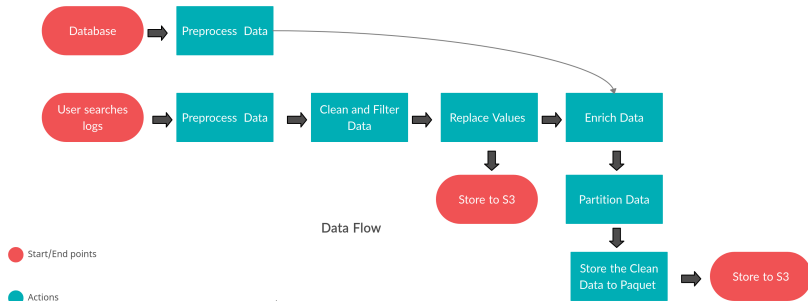

## ETL pipeline

## How data flows through the pipeline?

1. After the extraction of the useful data from the data sources, the data are ingested to the transform stage.
2. First, the duplicate records are removed along with the null records.
3. The data are then filtered, to remove any record that correspond to *brokerIDs*.
4. Null values for specific columns are replaced.
5. And finally the data are enriched with additional information.

# Data Flow Diagram

# Assignment implementation

1. The project is implemented using Python programming language (version: Python 3.8.5).
2. Pyspark is used since it can perform computations and transformations on data efficiently.
3. The project is accompanied by 2 bash scripts.
  - To activate a conda environment.
  - To manage the data directories.
4. The code is available on my github profile (<https://github.com/ninasiam>).

## Some Notes

- The data are preprocessed, in a separate application available in the project directory.
- Due to a datatype mismatch (eg. false/False) and the interpretation of json objects from pyspark, the json files could not be loaded correctly.
- I chose to process them separately, using spark RDDs, to keep the pipeline as clean as possible.
- I am pretty sure that a more efficient way exists (a parameter on pyspark json read function maybe), but at the moment this approach seemed to me straightforward.

## More on the implementation

- The main script is the `etl_main()`, where the `sparkSession` is initialized.
- The pipeline functionality (Export, Transform, Load) is implemented on the `ETL_fun.py` file.
- The json file preprocessing is performed by `preprocess_data.py`.

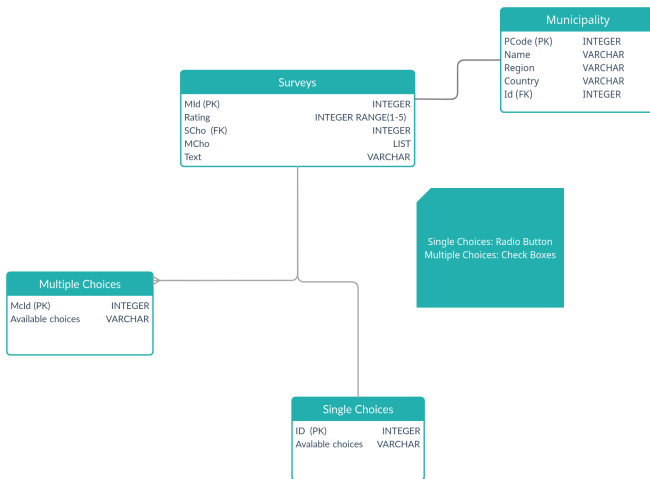

# Output files

- The output datasets (cleaned, enriched) are saved as parquet files.
- The Parquet is a column oriented storage file available to any project on the Hadoop ecosystem.
- Hence, aggregation queries are less time consuming compared to those on row oriented schemes.

## Survey on each Municipality feature

- Finally, a new feature is requested that regards various attributes of each municipality.
- The users of the portal will be asked to answer certain questions about each municipality concerning criminality etc.
- The functionality for this feature will be implemented in a relational database.
- In the following slide, my approach is presented.
- Note that, the relationship of entities surveys-Multiple Choices is *one to many*.

# Data Flow Diagram

# Final Comments

- For the data enrichment process only the country attribute is available on the enriched data.
- Comments and Docstrings are available on the each script.
